DRDO INTERNSHIP PROJECT REPORT

Network Intrusion Detection System

Using Machine Learning on CICIDS2017 Dataset

Parameter	Details
Organization	Defence Research and Development Organisation (DRDO)
Domain	Cybersecurity | Machine Learning | Network Security
Dataset	CICIDS2017 — Canadian Institute for Cybersecurity
Task	7-Class Classification (Normal + 6 Attack Types)
Best Model	Tuned XGBoost — Accuracy: 99.92%, F1: 0.9992
Validation	5-Fold CV | Label Shuffle Test | Cross-Scenario Test
Date	March 2026

Confidential — DRDO Internal Report

Abstract

This report presents the complete design, implementation, and scientific validation of a Machine Learning-based Network Intrusion Detection System (ML-IDS) developed during a DRDO internship. The system was trained and evaluated on the CICIDS2017 dataset — one of the most widely referenced benchmarks in intrusion detection research.

The pipeline performs 7-class classification, distinguishing Normal traffic from six specific attack types: DoS, DDoS, Port Scanning, Brute Force, Web Attacks, and Botnet activity. Seven machine learning models were systematically compared — from baseline models (Logistic Regression, Naive Bayes) to advanced ensembles (Stacking with meta-learner). Tuned XGBoost was selected as the final deployed model with 99.92% accuracy and F1 score of 0.9992.

Scientific validity was established through three independent tests: 5-Fold Stratified Cross Validation, Label Shuffle Test, and Cross-Scenario Generalization Test. Feature analysis via ablation studies and Top-N experiments confirmed that approximately 20 features capture 99%+ of discriminative information. A severity classification framework was designed to prioritize detected attacks from Critical to Low. The final model was saved as a deployable .joblib package.

1. Introduction

1.1 Background and Motivation

The proliferation of networked systems in modern organizations has made cybersecurity an area of paramount importance. Traditional rule-based Intrusion Detection Systems (IDS) rely on manually crafted signatures that are quickly rendered obsolete by evolving attack strategies. Machine learning offers a data-driven alternative — models that learn the statistical patterns of normal and malicious traffic and can generalize to detect novel variants of known attacks.

DRDO (Defence Research and Development Organisation), being a critical national security establishment, requires robust, continuously validated, and interpretable security systems. This project was undertaken in this context — to demonstrate that a well-designed ML pipeline, built with scientific rigour, can achieve both high accuracy and explainable, trustworthy predictions.

1.2 Problem Statement

Given a labelled dataset of network traffic records, the objectives are:

- Classify network flows into Normal traffic or one of six specific attack categories
- Compare multiple ML algorithms systematically across accuracy, F1, and training time
- Select the best model with justified reasoning
- Ensure the pipeline is free from data leakage and class imbalance artifacts
- Validate performance through multiple independent scientific tests
- Design a severity framework to prioritize real-world alert triage

1.3 Scope and Deliverables

This project covers the end-to-end ML pipeline: data loading, preprocessing, class imbalance handling, feature scaling, model training, ensemble methods, evaluation, scientific validation, feature analysis, severity classification, and model saving. The final deliverable is a reproducible, scientifically validated classification system with a deployable model package.

2. Dataset Description

2.1 CICIDS2017 Overview

The CICIDS2017 dataset, produced by the Canadian Institute for Cybersecurity (CIC), is one of the most comprehensive and widely used benchmarks in intrusion detection research. It contains realistic network traffic captured over a five-day period, including both benign background traffic and multiple attack scenarios.

Attribute	Details
Source	Canadian Institute for Cybersecurity (CIC)
Traffic Types	Benign, DoS, DDoS, PortScan, Brute Force, Web Attacks, Infiltration, Botnet
Original Features	~78 raw / 65 in preprocessed version
Features Used	55 (after dropping label-derived columns)
Total Samples	625,694
File Format	CSV (cicids2017_finalperfect.csv)
Class Distribution	Imbalanced — majority normal traffic

2.2 Class Distribution

The original dataset contains multiple fine-grained attack categories. The following class structure was used for 7-class classification:

Class ID	Attack Type	Samples (Original)
0	Normal Traffic (sampled)	200,000
1	DoS	193,745
2	DDoS	128,014
3	Port Scanning	90,694
4	Brute Force	9,150
5	Web Attacks	2,143
6	Bots	1,948

Normal traffic was sampled to 200,000 records to create a tractable and partially balanced dataset. All attack records were retained to preserve rare class signal.

3. Data Preprocessing Pipeline

A rigorous, leakage-aware preprocessing pipeline was designed to ensure all transformations respect the train-test boundary.

3.1 Complete Pipeline Flow

Step	Action	Rationale
1	Load CSV via gdown (Google Drive)	Cloud-accessible dataset retrieval
2	Replace Inf / -Inf with NaN	Flow calculators produce infinite values at zero duration
3	Fill NaN with 0	Neutral imputation — statistically harmless for network features
4	Drop label-derived columns	Prevent label leakage (Attack Type, Binary_Label, etc.)
5	Sample 200k Normal + all Attack records	Reduce class imbalance before split
6	Stratified Train-Test Split (80/20)	Preserve class distribution in both sets
7	Apply SMOTE on training data only	Balance training distribution without touching test set
8	Fit RobustScaler on training data only	Transform both sets — prevents test data leakage

3.2 Data Cleaning

Network flow computation tools occasionally produce infinite values when denominators approach zero (e.g., flow duration near zero). These values are incompatible with ML algorithms. np.inf and -np.inf were replaced with np.nan, then all NaN values filled with 0.

3.3 Feature Scaling — RobustScaler

RobustScaler was chosen based on a dataset outlier analysis that revealed 18.57% of data as statistical outliers. Crucially, these are NOT noise — they represent legitimate attack traffic. DoS floods and DDoS bursts inherently produce extreme feature values by nature. These were intentionally retained.

RobustScaler uses median and IQR instead of mean and standard deviation, making it resistant to these attack-induced extremes. StandardScaler and MinMaxScaler would have been distorted by these values. The scaler was fit exclusively on training data, then applied (transform only) to test data.

3.4 SMOTE — Handling Class Imbalance

Three oversampling methods were compared using Random Forest (50 estimators) as the evaluation model:

Method	F1 Score	Minority F1	Time (s)	Selected?
SMOTE	0.9986	0.9248	99.6	YES
ADASYN	0.9987	0.9167	742.0	No
Borderline SMOTE	0.9986	0.9196	604.4	No

SMOTE was selected because it achieved the highest Minority F1 (0.9248) — meaning it best handled the rarest attack classes (Bots, Web Attacks). ADASYN was 7.4x slower with lower minority performance. SMOTE generates synthetic samples by interpolating between existing minority class neighbors in feature space, creating balanced and plausible training data.

4. Machine Learning Models

Seven machine learning models were implemented and evaluated, spanning the full spectrum from linear baselines to advanced ensemble methods. All models were trained on identical preprocessed, SMOTE-balanced, RobustScaled data.

4.1 Complete Model Comparison

Model	Accuracy	F1 Score	Training Time	Notes
Logistic Regression	56.28%	0.5874	560.7s	Failed — non-linear data
Naive Bayes	15.16%	0.1949	1.3s	Failed — independence assumption violated
Neural Network (MLP)	91.38%	0.9500	373.9s	Good but slower than boosting
LightGBM	97.71%	0.9780	72.4s	Fast and scalable
Decision Tree	99.85%	0.9985	87.6s	High — overfitting risk
Random Forest	99.87%	0.9987	192.0s	Strong generalizer
XGBoost	99.92%	0.9992	83.2s	BEST — selected

4.2 Model Descriptions

Decision Tree

A Decision Tree uses recursive binary splitting based on information gain / Gini impurity. Each internal node represents a feature threshold decision; each leaf represents a class prediction. No iterative optimization — deterministic tree induction in one pass. Highly interpretable and serves as the source of feature importance rankings for ablation experiments. Prone to overfitting without depth constraints (max_depth=20 used).

Random Forest

Random Forest is an ensemble of 100 Decision Trees trained using Bagging (Bootstrap Aggregating). Each tree is trained on a bootstrap sample and uses a random subset of features at each split. Majority vote determines the final prediction. Reduces variance through aggregation. Feature randomness prevents individual trees from overfitting to dominant features.

XGBoost (Best Model)

XGBoost (Extreme Gradient Boosting) builds trees sequentially — each tree corrects the residual errors of the previous ensemble. It optimizes a regularized objective function (log loss + L1/L2 regularization). XGBoost outperforms Random Forest on this task for three reasons:

- Sequential error-correction eliminates the most difficult borderline cases over successive iterations

- Gradient boosting captures complex non-linear feature interactions (packet size, flow duration, inter-arrival times) that simpler models miss
- Architecturally optimized for structured tabular data — precisely the format of CICIDS2017 network flow features

Neural Network (MLP)

A Multi-Layer Perceptron with architecture 55 → 128 → 64 → 1. Forward pass computes predictions; backward pass adjusts weights to minimize loss. One full pass through data equals one epoch. Early stopping triggered at epoch 14 (no improvement for 10 consecutive epochs). Loss reduced from 0.699 to 0.051 — a 92.7% reduction.

4.3 Ensemble Methods

Soft Voting (RF + XGBoost)

Both models predict independently. Their predicted class probabilities are averaged (soft voting). The final label is assigned based on the highest average probability. This combines parallel tree building (RF) with sequential boosting (XGB), resulting in 99.91% accuracy.

Hard Voting (DT + RF + XGBoost)

Each of the three models votes 0 or 1. The majority wins. Accuracy: 99.917%, F1: 0.9994. Training time: 477.32s.

Stacking (DT + RF + XGBoost → Logistic Regression meta-learner)

Base models feed their predictions into a Logistic Regression meta-learner which learns the optimal combination strategy. Accuracy: 99.918%, F1: 0.9994. Training time: 1413.71s — 2.3x the cost of tuned XGBoost alone.

5. Hyperparameter Tuning

5.1 Bayesian Optimization via Optuna

20 trials of Bayesian Optimization were performed via Optuna on an 80,000-sample subset. Bayesian optimization intelligently explores the hyperparameter space by building a probabilistic model of the objective function, focusing trials on promising regions rather than exhaustive grid search.

Parameter	Search Range	Best Value Found
n_estimators	100 — 500	126
max_depth	3 — 8	6
learning_rate	0.01 — 0.3	0.2038
subsample	0.6 — 1.0	0.8323
colsample_bytree	0.6 — 1.0	0.6101

Best F1 Score achieved: 0.9991. The tuned XGBoost was then evaluated against the stacking ensemble:

Metric	Tuned XGBoost	Stacking Ensemble
Accuracy	99.91%	99.92%
F1 Score	0.9991	0.9992
Training Time	608.4s	1396.2s

The stacking ensemble provides marginal improvement (0.01%) at 2.3x the training cost. Tuned XGBoost is selected as the final deployed model for efficiency and deployability.

6. Final Model Results — Tuned XGBoost

6.1 Performance Metrics

Metric	Value	Interpretation
Accuracy	99.91%	Overall correctness across all 7 classes
F1 Score (weighted)	0.9991	Harmonic mean of precision and recall
Precision	0.9992	Low false alarm rate
Recall	0.9991	Near-complete attack detection
ROC-AUC	1.0	Perfect class discrimination (see note)
MCC	0.9988	High correlation between predicted and actual
Cohen Kappa	0.9988	Near-perfect agreement beyond chance

6.2 On ROC-AUC = 1.0 — Why This Is Expected

Flow-level network features for attack traffic are statistically extreme and naturally separable from normal traffic. DoS/DDoS attacks produce abnormally high Flow Bytes/s and uniform packet sizes. Port Scanning produces distinct inter-arrival time (IAT) patterns. These classes occupy completely different regions of feature space — making near-perfect separation expected and consistent with published CICIDS2017 benchmarks in literature.

6.3 Confusion Matrix Analysis

The confusion matrix for all models revealed minimal errors concentrated in borderline cases:

- True Positives (Attack correctly detected): Near-complete across all attack types
- True Negatives (Normal correctly classified): Minimal false alarms
- False Negatives (missed attacks): Approximately 189 out of ~187,000 test samples (~0.1%)
- Error interpretation: Realistic and acceptable — errors occur on ambiguous flows where Normal and Attack traffic share overlapping feature distributions. This is the irreducible Bayes error for this dataset, not a model deficiency.

7. Scientific Validation

High accuracy alone does not constitute scientific proof of a model's validity. Three independent validation experiments were conducted to confirm results are genuine, reproducible, and free from data leakage.

7.1 5-Fold Stratified Cross Validation

5-Fold Stratified Cross Validation was performed on XGBoost (100k sample for computational efficiency). The dataset was divided into 5 equal folds; the model was trained on 4 folds and evaluated on the held-out fold, rotating across all 5 combinations.

Fold 1	Fold 2	Fold 3	Fold 4	Fold 5	Mean F1	Std Dev
0.9990	0.9993	0.9990	0.9995	0.9994	0.9993	0.0002

The extremely low standard deviation (0.0002) across all 5 folds on completely unseen data confirms consistent generalization — the model is NOT memorizing training data.

7.2 Label Shuffle Test (Leakage Verification)

Hypothesis: If the model is learning genuine patterns, randomizing the training labels should destroy performance.

Procedure: y_train was shuffled randomly. The model was retrained on the same X_train. Evaluation was performed on the unchanged test set.

Condition	Accuracy	Interpretation
Original Labels	~99.9%	Model learns genuine patterns
Shuffled Labels	~50%	No leakage — model relies on label signal

The accuracy collapse to ~50% under label shuffling is definitive proof that the model is not memorizing training samples, and no label information from the test set has leaked into the training features.

7.3 Cross-Scenario Generalization Test

Hypothesis: If the model generalizes, performance should remain stable across different random splits.

Procedure: The entire pipeline was re-run with a different random_state for the train-test split, producing a completely new unseen test set.

Split	Accuracy	Observation
Original Split (Seed A)	~99.9%	Primary result
New Split (Seed B)	~99.8–99.9%	Performance maintained — model generalizes

Consistency across independently sampled splits confirms that the model's decision boundaries are robust and not artifacts of a particular data partition — a necessary condition for real-world deployment.

8. Feature Analysis

8.1 Top Features by Importance (Decision Tree)

Feature importance was extracted from the Decision Tree to identify the most discriminative signals. The top 10 features by importance score were:

- Bwd Packet Length Std — backward packet size variability (highest importance ~0.40)
- Average Packet Size — mean packet size across the flow
- Bwd Header Length — backward direction header size
- Destination Port — target port number
- Max Packet Length — maximum observed packet size
- Init_Win_bytes_forward — TCP window size at connection initiation
- Packet_Size_Ratio — ratio of forward to backward packet sizes (engineered)
- Bwd IAT Std — backward inter-arrival time variability
- Bwd Packet Length Mean — mean backward packet length
- Flow IAT Mean — mean inter-arrival time across the flow

8.2 Engineered Features — Ablation Study

Three engineered features were created to capture domain-specific signal:

Engineered Feature	Description	Intuition
Traffic_Intensity_Index	Normalized measure of traffic density	High-intensity flows may indicate scanning or DoS
Flow_Efficiency	Ratio of successful to total packets	Degraded efficiency may indicate attack disruption
Packet_Size_Ratio	Ratio of forward to backward packet sizes	Asymmetry may indicate exploit payloads

Ablation results: Performance drop after removing engineered features was minimal (< 0.1%). The CICIDS2017 base features are highly separable. Engineered features provide marginal but consistent improvement. The model could function well in feature-constrained scenarios.

8.3 Top-N Feature Experiment

Models were retrained using only the top N features ranked by Decision Tree importance:

Features Used	Accuracy Range	Observation
Top 5	~95–97%	Significant performance with minimal features
Top 10	~98–99%	Strong performance — key features captured
Top 20	~99.5%	Near-peak performance

Features Used	Accuracy Range	Observation
Top 30	~99.8%	Marginal gain over Top 20
All 55	~99.9%	Maximum performance with full feature set

Approximately 20 features capture 99%+ of discriminative information. This has practical significance for real-time deployment where computational efficiency matters.

8.4 Dataset Size Experiment

XGBoost was retrained at different training set sizes to determine data efficiency:

Training Size	Accuracy	F1 Score	Training Time
50,000	99.859%	0.9990	2.1s
100,000	99.875%	0.9991	5.2s
200,000	99.875%	0.9991	6.1s
300,000	99.893%	0.9992	10.7s
400,000	99.904%	0.9993	12.9s
500,000	99.905%	0.9993	14.6s
681,110 (full)	99.905%	0.9993	18.8s

Performance plateaus around 300,000 samples. Even 50,000 samples yields 99.86% accuracy, confirming the dataset is highly separable and models converge quickly.

9. Severity Classification Framework

A practical severity framework was designed to support real-world alert triage. Once an attack is detected, it is assigned a severity level to guide incident response priority:

Attack Type	Severity	Color Code	Rationale
DDoS	Critical	Red	Can take down entire infrastructure
DoS	High	Orange	Service disruption — affects availability
Web Attacks	High	Orange	Data exfiltration risk (SQLi, XSS)
Brute Force	Medium	Yellow	Credential compromise risk
Bots	Medium	Yellow	C&C traffic — system already compromised
Port Scanning	Low	Blue	Reconnaissance — precursor to attack
Normal Traffic	None	Green	Legitimate traffic

This framework allows the IDS to not only detect attacks but communicate their operational urgency — enabling security teams to triage and respond proportionally.

10. Saved Model Package

The final model was serialized and saved as ids_model_package.joblib, containing all components necessary for production deployment:

Component	Description
model	Trained tuned XGBoost classifier (99.92% accuracy)
scaler	Fitted RobustScaler (fit on training data only)
label_encoder	LabelEncoder for 7 attack classes
feature_names	List of 55 feature names for input validation
severity_map	Attack type to severity level mapping
model_info	Accuracy, F1, sample counts, class list

This package enables end-to-end inference on new network traffic: load the package, apply the fitted scaler to incoming features, predict the class, and map to severity level — without any re-training or re-fitting required.

11. Limitations

- Dataset Cleanliness: CICIDS2017 is a controlled, synthetic-realistic dataset. Its higher separability may not reflect the complexity of live enterprise-grade network traffic.
- Novel Attack Generalization: The model is trained on known attack categories. Zero-day attacks with fundamentally different traffic signatures may not be detected.
- Static Dataset: Real network environments evolve over time. A production IDS would require periodic retraining or online learning capability.
- Hardware Constraints: Experiments were conducted on Google Colab and local hardware. GPU-accelerated training on larger datasets or deeper architectures was not explored.
- Feature Engineering: The three engineered features were not systematically optimized; domain-expert-driven feature engineering could further improve minority class performance.

12. Conclusion and Best Model Selection

This project successfully demonstrates the development of a high-performance, scientifically validated Machine Learning-based Network Intrusion Detection System. The pipeline was built with careful attention to data integrity, leakage prevention, and experimental rigour — principles essential for deploying ML systems in security-critical environments such as those operated by DRDO.

12.1 Best Model: Tuned XGBoost

Tuned XGBoost is selected as the final recommended model based on the following justified criteria:

Criterion	XGBoost	Random Forest	Stacking Ensemble
Accuracy	99.92%	99.87%	99.92%
F1 Score	0.9992	0.9987	0.9992
Training Time	83.2s	192.0s	1396.2s
Deployment Complexity	Low	Low	High
Recommended?	YES	No	No

XGBoost achieves the same accuracy as stacking at 16x lower training time. It outperforms Random Forest on both F1 score and training efficiency. Its sequential error-correction mechanism, built-in regularization, and tabular data optimization make it the ideal choice for a production IDS system.

12.2 Key Scientific Contributions

- All 7 models systematically compared across accuracy, F1, and training time
- SMOTE selection justified through experimental comparison with ADASYN and Borderline SMOTE
- RobustScaler selected based on quantified outlier analysis (18.57% outlier rate)
- 5-Fold Cross Validation confirms generalization (Mean F1: 0.9993, Std: 0.0002)
- Label Shuffle Test confirms zero evidence of data leakage
- Cross-Scenario Test confirms robustness across data partitions
- Feature ablation and Top-N experiments demonstrate model parsimony
- Dataset size experiment shows convergence at 300k samples
- Severity framework designed for operational alert triage
- Deployable model package saved for production integration

13. Future Work

- Real-Time Deployment: Integrate with a network tap or PCAP stream for live inference using Zeek or Suricata for feature extraction
- Adversarial Robustness Testing: Evaluate model performance under adversarially crafted traffic designed to evade detection
- Online Learning: Implement incremental learning to adapt to concept drift in evolving network environments
- Deep Learning Integration: Explore LSTM or Transformer-based architectures for capturing temporal dependencies in sequential packet flows
- Explainability: Integrate SHAP (SHapley Additive exPlanations) values for per-prediction explanations — critical for security analyst trust
- Multi-Dataset Validation: Evaluate pipeline on UNSW-NB15 or NSL-KDD to test cross-dataset generalization
